In this article, a case of clear cell sarcoma of the flexor hallucis longus in a 42-year-old woman is presented. The patient had previously been treated for suspected bursitis of the big toe. After extensive investigation, Lisfranc amputation was performed in order to achieve tumor-free margins. No adjuvant therapy was administered. At 5-year follow-up, there was no evidence of tumor recurrence or metastatic disease. The patient was functional in a modified shoe without the need for prosthesis. *Adv Orthop* 2011;**2**(4):156–60.

Originally described by Enzinger in 1965, clear cell sarcoma (CCS) is a high-grade soft tissue sarcoma seen in adolescents and young adults, with melanocytic differentiation typically involving tendons and aponeuroses [1]. In the past, CCS was called malignant melanoma of the soft parts, because it bears histological and immunohistochemical similarities to amelanotic melanoma and cellular blue nevus; however, it is a unique lesion distinct from cutaneous malignant melanoma [2,3]. CCS can be distinguished from melanoma by molecular biology, such as fluorescence *in situ* hybridization (FISH) and reverse transcriptase polymerase chain reaction (RT-PCR) [2–5]. The chromosomal translocation t(12;22)(q13;12) or the resultant fusion gene EWSR1-ATF1 is the hallmark of CCS [6–9].

In early reports, CCS was said to predominate in women, but several recent reports show an equal distribution between the sexes [2,3,10,11]. CCS occurs predominantly in young patients between 15 and 35 years of age [12], and the distal extremities are the main sites of involvement. CCS is more prevalent in white people than in African Americans and Asians [10].

The prognosis of CCS is poor, owing to a high percentage of regional lymph node metastases and distant metastases. An incidence of metastasis of 60–70% has been reported [13]. Typically, the tumor will recur locally approximately 2.5 years after treatment is initiated and will metastasize after 3–4 years. However, metastases have been seen up to 30 years after the initial diagnosis [14,15].

Wide excision or radical resection is the surgical treatment of choice for CCS according to the tumor margins [16–19], although other methods, including radiation, chemotherapy, arterial limb perfusion, and perilesional infusion of interferon α-2b (IFN-α-2b), have also resulted in apparent cure [20–22].

Beyond the soft tissues, CCS has also been described at other anatomical sites, including bone [23–30], pleura [31], kidney [32], penis [33], and gastrointestinal tract [34–42]. In this article, we report a case of CCS arising in the flexor hallucis longus tendon of a 42-year-old woman, and discuss the approach to diagnosis and treatment.

Case study

A 42-year-old woman with a diagnosis of CCS of the soft tissue in the first metatarsophalangeal joint was admitted to our clinic for definitive treatment. Her medical history was not contributory. One year before, she had presented with a soft tissue mass close to the first metatarsophalangeal joint, which increased until it was 4 cm and became painful. The presumptive diagnosis was bursitis of the great toe. She was treated with orthopaedic measures (e.g. shoe insoles and physiotherapy) and non-steroidal anti-inflammatory drugs, but experienced no improvement in the pain. Her doctor requested radiographs (**Figure 1**) and magnetic resonance imaging (MRI), which showed a soft tissue mass with no calcification arising in association with the flexor hallucis tendon, with hypointensity on T1-weighted images, hyperintensity on T2-weighted images, and gadolinium uptake (**Figure 2**). Fine-needle aspiration (FNA) was non-diagnostic and open excisional biopsy was carried out, followed by angular correction of the fifth metatarsal during the same surgery. The pathology report confirmed the presence of

Figure 2. Magnetic resonance image showing a mass arising in association with the flexor hallucis longus tendon.

CCS with positive margins. The tumor size was 4.0×2.0×1.2 cm, with 10 mitotic cells per field, no necrosis, and malignant grade II/III. The tumor cells were pleomorphic and grew in sheets and fascicles. Immunohistochemistry showed neoplastic cells positive with HMB-45 and reactive to antibody against S100 protein. Detection of t(12;22)(q13;q12) was performed using FISH.

Figure 3. A: Surgical wound after excisional biopsy on the medial aspect of the first metatarsophalangeal joint. **B:** Surgical wound after angular correction on the dorsal aspect of the fifth metatarsophalangeal joint.

Upon physical examination at our clinic, 1 month after the biopsy, there was a surgical wound on the medial aspect of the first metatarsophalangeal joint (**Figure 3A**), without signs of infection or swelling, and another wound on the dorsal aspect of the fifth metatarsophalangeal joint (**Figure 3B**), also without any sign of infection. There were no other relevant signs or symptoms. Whole-body computed tomography showed no evidence of metastatic disease. Positron emission tomography and MRI demonstrated only postoperative changes.

Figure 4. A: Intraoperative photograph. Lisfranc amputation was performed in order to achieve tumor-free margins. B: Intraoperative photograph. The tibialis anterior and extensor common tendons were reattached proximally.

Figure 5. Postoperative radiograph. Lateral view.

After an interdisciplinary meeting between an oncologist, a radiologist, and orthopaedic oncology surgeons, the patient consented to undergo radical resection with Lisfranc amputation for definitive treatment (**Figure 4A**). Tibialis anterior and common extensor tendons were reattached to the second and third cuneiform bone remainders with two 3.5-mm suture anchors (Statack; Zimmer®, Warsaw, IN, USA; **Figure 4B)**. Intraoperative biopsy showed no tumor cell infiltration of the margins, and this was confirmed at definitive analysis of the resected tumor.

There were no intra- or postoperative complications (**Figure 5**). A well-padded posterior splint was placed to protect the amputation site and provide immobilization. The patient started partial weight-bearing at 4 weeks postoperatively, and total weight-bearing without crutches in a modified shoe at 6 weeks (**Figure 6**). At 5 years of follow-up, there was no evidence of recurrence or metastasis and the patient had no significant limitation of her daily activities.

Discussion

CCS is a slow-growing malignant tumor of soft tissue. The diagnosis of CCS is often difficult because it is uncommon and has an unusual histopathology. On MRI, it appears as a well-circumscribed soft tissue mass, rarely invading adjacent bones, with variable signal intensity on T1-weighted and T2-weighted MRI. CCS should, however, be suspected when the lesion displays high signal on all sequences, including fat-saturation techniques [43,44], and also when calcifications, fluid-fluid levels, and marked hypointensities are absent within the mass [45].

Tumor response to the immunoperoxidase stains for S-100 and HMB-45 is helpful in diagnosis. It is important to differentiate between CCS and melanoma, because their prognosis and treatment differ substantially. However, this is not always possible on histological/immunohistochemical grounds alone [46]. In some situations, a genetic study is very helpful, because the t(12;22) translocation has never been reported in cutaneous melanoma [3,4,9]. Coindre et al. obtained positive results in 93% of CCS patients who were diagnosed by RT-PCR on paraffin-embedded tissues [9]. PCR-negative tumors can be explained by variant chromosomal translocations, such as t(2;22) with a EWS-CREB1 fusion, as reported recently [35]. Some PCR-negative tumors may also be melanoma with total regression of the primary or the superficial component. FISH using break-apart probes for EWS rearrangement is a good alternative to confirm the diagnosis. It is applicable for paraffin-embedded tissues and can be used overnight. However, it is not specific for CCS, because other tumors that show EWS rearrangement, such as Ewing sarcoma, desmoplastic round cell tumor, extraskeletal myxoid chondrosarcoma, and some myxoid/round cell liposarcomas, may show similar signals [9].

The prognosis for patients with CCS is poor, and they have a high propensity for regional lymph node and distant

Figure 6. Postoperative photograph. The patient was able to walk in a modified shoe without the use of prosthesis.

metastases. Recurrence and metastases have been reported up to 30 years after resection of the initial tumor. Lifelong surveillance is necessary for the early detection of recurrent disease. Metastases mainly occur in the regional lymph nodes and lungs, but can also affect brain, bone, or liver [10,47,48]. The use of sentinel lymph node biopsy has been proposed as an effective means of determining early occult regional metastases [49]. Poor prognostic indicators include a tumor size ≥5 cm, presence of metastases, and necrosis [11,17,50,51]. Recent large studies have added the depth of the tumor, sex, Tumor–Node–Metastasis stage, surgical margin, mitotic index, and histological grade to the list of prognostic factors [9,52].

Treatment by radical resection or amputation appears to have the most favorable results when a wide surgical margin is impossible to achieve or when the reconstruction is not functional [19]. Therefore, wide surgical resection has recently been proposed as the treatment of choice when the surgical oncology margin is adequate [53].

The beneficial effects of adjuvant chemotherapy and radiotherapy in CCS have not been fully evaluated [50]. Adjuvant radiotherapy has been used for improving local control, especially in the case of questionable resection margins [2,17,18,54]. Kawai et al. have argued that it should probably be assumed that patients with a tumor size >5 cm have micrometastases at the time of presentation, as these patients could benefit from adjuvant chemotherapy [52]. As CCS of tendons and aponeuroses shares many characteristics with malignant melanoma, investigation into the use of immunotherapy is warranted [11]. Steger reported a 17-month complete remission period in one patient treated with intralesional injection of IFN-α-2b [13].

In order to achieve tumor-free surgical margins, and owing to previous inadequate surgery of the first and fifth metatarsals, limb salvage surgery was not thought to be sufficient in our case; therefore, Lisfranc amputation was chosen. Excisional biopsy is not an appropriate option for diagnosis when malignancy is possible. In our patient, a tru-cut biopsy should have been performed to make the diagnosis instead of FNA, and excisional biopsy should not have been performed.

The Lisfranc amputation level is a viable option to preserve the length of the foot and offers the potential for retention of plantar load-bearing tissues, allowing patients to be functional in a modified shoe rather than a prosthesis [55]. When the decision is made to perform a Lisfranc amputation, one should consider the musculotendinous structures that are going to be encountered during this procedure. These structures are important to maintain the position and function of the foot. The tibialis posterior muscle provides inversion and plantar flexion of the foot. The insertion should be preserved because its main navicular insertion is not encountered during the procedure. The tibialis anterior tendon is a powerful dorsiflexor of the foot. If disturbed, it should be reattached to the proximal aspect of the medial cuneiform to preserve function. The peroneus brevis and tertius muscles are powerful evertors of the foot, and their insertions should be preserved if possible. Equinovarus deformity can result because of the loss of most of the dorsiflexors and the shortening of the foot. Ulceration of the distal stump can be a direct result of equinovarus deformity. Achilles tendon tenotomy or lengthening may be necessary to avoid this deformity [56].

Our case of CCS was misleading initially because of its location and clinical presentation. When a malignant tumor is possible, management including biopsy should be performed by an experienced multidisciplinary team in order to achieve good results [57].
